# Directional Antennas in Mobile Ad Hoc Networks

- Great performance benefits if directional antennas utilized effectively in mobile ad hoc networks
  - Directional antennas can result in high complexity
    - Adaptive beam-forming, management of beam pointing
    - Complex neighbor discovery, need for location information
  - Our focus: fixed-beam antenna subsystems exploited with relatively simple protocols/algorithms
    - Multiple fixed-beam directional antennas at node
- 
- together give node **omni-directional coverage** in azimuth
  - **separate transceiver** for each beam
  - number of beams may differ for different nodes

- Characteristics of node with multiple fixed beams/transceivers
  - Cost is multiple transceivers rather than signal processing
  - No management of beam-pointing by protocols required
  - No beam switching at transceiver front end is required
  - Neighbor discovery same as with omni-directional antennas
  - No explicit location information required
- Necessary/desirable properties of MAC protocol
  - MAC management of transceivers is consistent with physical-layer constraints of antenna subsystems
  - MAC mitigates unique performance limitations arising due to physical-layer characteristics of antenna subsystems
  - Same MAC supports nodes with any number of beams

# Relationship Between Physical-Layer Characteristics and MAC-Layer Design

- Multiple antenna subsystems at node result in **co-site interference** among transceivers

The diagram shows a central node represented by a square with a vertical line extending downwards. Two antennas, depicted as trapezoidal shapes, are positioned above the node. A dashed curved arrow originates from the left antenna and points towards the right antenna, indicating a signal path or interference between the two antennas.
- Signal energy from one transceiver coupled into another transceiver through antennas, other EMI mechanisms
- Possible MAC-layer solutions:
  - no TX at node when RX expected by any transceiver at node
  - TX limited only based on characteristics of antenna subsystems
- Use of directional antennas exacerbates the **receiver blocking problem** in packet radio network
  - MAC-layer solution must address this problem for best performance

# System Design

- Characteristics of nodes in network
  - Node with omni-directional antenna has one half-duplex transceiver
  - Node with multiple beams has one half-duplex transceiver per beam
  - Collision-avoidance (RTS-CTS) random-access MAC protocol
  - Direct-sequence spread-spectrum packet transmission
- “Baseline” MAC protocol addresses co-site interference problem
  - Multiple frequency channels:
    - One control channel for RTS, CTS packets
    - One or more traffic channels for DATA, ACK packets
  - Intercepted CTS blocks local use of a frequency channel in beam (mitigates hidden-terminal problem)
  - Exponential back-off algorithm (response to perceived busy terminal)
  - Single MAC layer controls transceivers of all beams at a node
  - Expected packet reception at any beam’s transceiver blocks all transmissions at node

## Example of Eight-Node Network

- Two frequency channels
- Two scenarios considered
  - Network I: All nodes have omni-directional antennas
  - Network II: Nodes 0-3 have three 120-degree beams each
- Beam orientation in network II isolates active 0-1 link from active 2-3 link
- Poisson traffic at each node
  - Node 0 to node 1: rate  $G$
  - Node 2 to node 3: rate  $G$
  - Nodes 4-7 to adjacent corners: rate  $I/2$
- Performance measure
  - Link-layer throughput, no routing
  - Throughput per node for 0 and 2

## Performance with Baseline MAC Protocol

- Directional antennas reduce MAI on links of interest
- With no interfering traffic, expect doubling of throughput with directional antennas
  - Anticipated doubling is observed
- With heavy interfering traffic, expect greater benefit from directional antennas
  - **Opposite** phenomenon is observed

## Performance with Baseline MAC Protocol

- Throughput more sensitive to interfering traffic if nodes 0-3 employ directional antennas
  - Introduction of directional antennas actually *decreases* throughput in this network if interfering traffic is heavy
- Phenomenon is a manifestation of the **receiver blocking problem**
  - Transmitter of RTS erroneously infers “busy radio” from missing CTS, initiates back-off algorithm
  - Problem also arises with omni-directional antennas
  - Random placement of interferer more likely to cause problem for node with directional antenna than with omni antenna
  - So problem has greater impact on performance if some nodes employ directional antennas

## A Simple Solution: the negative CTS

- A node with all local traffic channels blocked for a beam can still transmit on control channel
- Transmitter can be more aggressive in retransmission attempts if intended receiver has blocked channels than if it is busy
- Modified MAC protocol
  - Transmitter still employs original back-off algorithm in response to missing CTS
  - Receiver with all traffic channels blocked responds to RTS with negative CTS (NCTS) containing information about channel availability
  - Transmitter exploits NCTS information to determine aggressiveness of retransmission algorithm
    - Algorithm accounts for information in recent NCTS packets
- Modified MAC protocol improves performance with both directional antennas and omni-directional antennas
  - Greater improvement occurs for network employing some nodes with multiple directional antennas

## Performance with Modified MAC Protocol

More than two-fold increase in throughput under heavy-traffic conditions

## Conclusions

- Properly designed MAC protocol mitigates co-site interference at node with multiple fixed-beam antennas
- Packet radio network including nodes with directional antennas is more vulnerable to receiver-blocking problem than network with only omni-directional antennas
- Alternative collision-avoidance MAC protocol mitigates receiver blocking by using negative CTS control packet
  - Improves performance of network with only omni antennas
  - Provides greater improvement if some nodes have directional antennas
